AUDITORY AND LINGUISTIC PROCESSES IN THE
PERCEPTION OF INTONATION CONTOURS

MICHAEL STUDDERT-KENNEDY

and

KERSTIN HADDIN

Haskins Laboratories New Haven, Connecticut

The fundamental frequency contour of a 700-msec, vocoded utterance, "November" [nɔvəmbr], was systematically varied to produce 72 contours, different in \( f_0 \) at the stress and over the terminal glide. The contours were recorded (1) carried on the speech wave, (2) as modulated sine waves. Swedish and American subjects classified (1) both speech and sine-wave contours as either terminally rising or terminally falling (psychophysical judgments), (2) speech contours as questions or statements (linguistic judgments). For both groups, two factors acted in complementary relation to govern linguistic judgments: perceived terminal glide and \( f_0 \) at the stress. Listeners tended to classify contours with an apparent terminal rise and/or high stress as questions, contours with an apparent terminal fall and/or low stress as statements. For both speech and sine waves psychophysical judgments of terminal glide were influenced by earlier sections of the contour, but the effects were reduced for sine-wave contours, and there were several instances in which speech psychophysical judgments followed the linguistic more closely than the sine wave judgments. It is suggested that these instances may reflect the control exerted by linguistic decision over perceived auditory shape.

INTRODUCTION

The perception of spoken language may be conceived as a process conducted at several successive and simultaneous levels. Auditory, phonetic, phonological, syntactic, and semantic processes form a hierarchy, but decisions from higher levels also feed back to correct or verify tentative decisions at lower levels and to construct the final percept. Suitable experiments (e.g. Warren, 1970) may demonstrate the control exercised by higher on lower level decisions, and the partial determination of phonetic shape by phonological and syntactic rules is readily assumed by some linguists (e.g., Chomsky and Halle 1968, p. 24). However, the auditory level, itself a complex of

interactive processes by which an acoustic signal is converted into a representation suitable for input to the phonetic component (Fourcin, 1972), is commonly taken to be relatively independent.

A few studies have questioned this assumption. Ladefoged and McKinney (1963), for example, showed that judgments of the loudness of words presented in a carrier sentence may be more closely related to the work done upon them in phonation, that is, to their degree of stress, than to their acoustic intensity. Allen (1971), replicating and extending the experiment, showed that both acoustic level and inferred vocal effort may serve as cues for the loudness of speech, and that individuals differ in the weight they assign to these cues. Evidently, loudness judgment of speech may entail a relatively complex process of inference, drawing upon more than one level of analysis. The same may be true of pitch judgment: Hadding-Koch and Studdert-Kennedy (1963, 1964, 1965) found that auditory judgments of listeners, asked to assess fundamental frequency (f0) contours imposed synthetically on a carrier word, seemed to be influenced by linguistic decisions. The present experiment extends this earlier work and, by examining the relations among sections of the f0 contour used in judging an utterance as a question or statement, attempts a more detailed understanding of auditory-linguistic interaction in the perception of intonation contours.1

The starting point for the study is the importance commonly attributed to the terminal glide as an acoustic cue for judgment of an utterance as a question or statement. Two related sets of questions present themselves. The first concerns the basis for auditory judgments of the glide. From our earlier study (Hadding-Koch and Studdert-Kennedy, 1963, 1964, 1965) it was evident that listeners frequently judge a falling glide as rising and a rising glide as falling. Is the origin of this effect auditory (psychophysical) or linguistic? Our study left the question unanswered. There, we systematically manipulated the contour of an utterance by varying f0 at the stress peak, at the “turning point” before the terminal glide, and at the end point. We then asked listeners to classify each contour as (1) question or statement (linguistic judgment), (2) having a terminal rise or fall (psychophysical judgment). The two tasks yielded remarkably similar results: whether judging the entire contour linguistically or its terminal glide psychophysically, listeners were influenced in similar ways by the overall pattern of the contour. The outcome suggested that auditory judgments may have been controlled, in part, by linguistic judgments. But the reverse interpretation—that linguistic judgments of the entire contour were controlled by auditory judgments of the terminal glide—is equally plausible as long as we do not know the auditory capacity of listeners for judging the terminal glides of matched non-speech contours. The present study attempts to resolve this ambiguity by in-

1 The acoustic correlates of intonation are said to be changes in one or more of three variables: fundamental frequency, intensity, and duration, with variations in fundamental frequency over time being the strongest single cue (Bolinger, 1958; Denes, 1959; Fry, 1968; Lehiste, 1970; Liberman, in press). The present study is concerned with only one of these variables, fundamental frequency, and the term “intonation contour” refers exclusively to contours of fundamental frequency.
cluding the necessary non-speech judgments. Effects observed only in the two types of speech judgment would then be compatible with the first interpretation, while effects observed in all three types of judgment would be compatible with the second.

At the same time, this study broaches a second, related set of questions. These concern the roles of the various sections of the contour in determining linguistic judgments. Previous studies, naturalistic and experimental, have suggested that listeners make use of an entire contour, not simply of the terminal glide, in judging an utterance (see Garding and Abramson, 1965; Hadding-Koch, 1961; Hadding-Koch and Studdert-Kennedy, 1963, 1964, 1965). For example, spectrographic analyses of Swedish speech have shown that, in this language, "yes-no" questions normally display not only a terminal rise, but also an overall higher f, than statements (Hadding-Koch, 1961). Other utterances in which the speaker wants to draw the listener's special attention also display an overall high f, and a terminal rise: in listening tests the labels "question," "surprise," "interest" have been found to be interchangeable (Hadding-Koch, 1961, pp. 126 ff.). If a speaker is not interested or is asking a question to which he thinks he knows the answer, his utterances tend to display a lower overall f, and a falling terminal glide, similar to those of statements.

The importance of the entire contour may be reflected in the phonetic description. If four f, levels are postulated, with arrows showing the direction of the terminal glide, the intonation contour of a typical Swedish "yes-no" question could be described with one number at the beginning of the utterance and two at the stress, as 3 44 21 (the superscript 3 indicates the end point of the terminal glide) or, if less "interested", as 2 33 21. A neutral statement would be best described as 2 33 11, or even 2 22 11, though the latter might also indicate a certain indifference. Much the same statement contour is typical of American English. However, questions in this language are said to display a more or less continuously rising contour (Pike, 1945; Hockett, 1955) which might be described as 2 22 31 or 2 33 31. Similar contours occur in Swedish echo-questions.¹

These naturalistic observations of speech are, in general, consistent with results of our experimental study of perception (Hadding-Koch and Studdert-Kennedy, 1963, 1964, 1965). Swedish listeners selected a typical Swedish question (2 44 21) among their preferred question contours, and a lower contour with a level terminal

¹ Many workers who have reported, for various languages, that the same intonation is used in questions as in statements, seem to have been anxious to exclude all emotional "overtones" and therefore told their subjects to speak in a neutral voice. The result is that, in the absence of grammatical Q-markers, utterances sound like statements. A "neutral" intonation is not enough to convey, as sole cue, the impression of a question. If a question is asked merely for form's sake, with no particular interest in the answer, no difference in intonation is to be expected from that of a statement.

² We write two numerals at the stress and one at the turning point, even though they may be on the same "level" (intonation level, f, level), cf. Delattre, 1963; Hockett, 1955.

³ Compare the similar difference in intonation contours for French suggested by Léon (1972).
glide (2 33 l→) among their preferred statements (they would probably have preferred 2 33 11 for a statement had this contour been included). The North Americans listeners also preferred 2 44 21 for a question and 2 33 1→ for a statement, but they were more uncertain (in less agreement with one another) than the Swedish listeners—perhaps because the contours were based on Swedish speech and did not include, for example, a typical American English question.

Granted, then, the importance of the entire contour, we may now ask how its various sections work together to control linguistic judgment. Here, let us recall a central finding of our previous study, namely that there was perceptual reciprocity among various sections of a contour: listeners would trade a high f0 at one point in the utterance for a high f0 elsewhere. For example, an utterance with a relatively high f0 at peak or turning point required a smaller terminal rise to be heard as a question than an utterance with relatively low f0 at peak or turning point. We may interpret this reciprocity in either of two ways. The first interpretation assigns only auditory status to peak and turning point and assumes their linguistic role to be indirect. Thus, an utterance is marked as question or statement by its apparent terminal glide. Earlier sections of the contour are important only insofar as they alter (by some mechanism to be specified) listeners' perceptions of that glide and thereby give rise to the observed reciprocity effects. Lieberman's (1967) account of our results rests squarely on these assumptions. He selects an "analysis-by-synthesis" mechanism to account for the reciprocity.

An alternative interpretation assigns a direct linguistic function to peak and turning point. An utterance is marked as question or statement not only by its terminal glide, but also by the f0 pattern over its earlier course. Listeners discover at least two acoustic cues within a contour, either or both of which may control their linguistic decision. The weighting of these cues (by some unknown mechanism) gives rise to the reciprocity observed in linguistic judgments.

A second purpose of this study was to distinguish between these accounts, again by extending our earlier work to include judgments of the terminal glides of matched non-speech contours. Effects present in all three types of judgment would then require the first interpretation but would exclude an account, such as that of Lieberman (1967), that invoked specialized speech mechanisms. Effects present only in the two types of speech judgment would be compatible with both the first interpretation and Lieberman's hypothesized mechanism. Effects present only in the linguistic judgments would require the second interpretation.

Finally, an additional purpose of the study was to extend our cross-linguistic comparison of Swedish and American English listeners. We therefore enlarged the set of contours to include typical questions and statements from both American English and Swedish.

**Method**

The stimuli were prepared by means of the Haskins Laboratories Digital Spectrum
Manipulator (DSM) (Cooper, 1965). This device provides a spectrographic display of a 19-channel vocoder analysis, digitized to 6 bits at 10 msec. intervals, and permits the experimenter to vary the contents of each cell in the frequency-time matrix, before re-synthesis by the vocoder. For the present study we were interested in the channel that displayed the time course of the fundamental frequency of the utterance, since it was by manipulating the contents of this channel that we varied $f_0$.

The utterance “November” [no'vembs] was spoken by an American male voice into the vocoder and stored in the DSM. $f_0$ was then manipulated over a range from 85 c.p.s. to 220 c.p.s. The $f_0$ values at the most important points of the contours (starting point, peak, turning point, and end point) were chosen to represent four different $f_0$ levels of a speaker with a range from 65 c.p.s. to 250 c.p.s. The four levels were based on a previous analysis of a long sample of speech by a speaker with this particular range (Hadding-Koch, 1961, pp. 110 ff.).

The contours are schematized in Fig. 1. They range between two poles that may be marked 2 44 3 1 and 2 11 11. All contours start on a $f_0$ of 130 c.p.s. (level 2), sustained for 170 msec. over the first syllable. They then move, during 106 msec., to one of three peaks: 130 c.p.s. (L, or low, level 2), 160 c.p.s. (H, or high, level 3), 200 c.p.s. (S, or superhigh, level 4). They proceed, during 127 msec., to one of four turning points: 100 c.p.s. (high level 1), 120 c.p.s. (level 2), 145 c.p.s. (low level 3), 180 c.p.s. (high level 3). Finally, they proceed, during 201 msec., to one of six-endpoints: 85 c.p.s. (level 1), 100 c.p.s. (high level), 120 c.p.s., 145 c.p.s., and 220 c.p.s (level 4). Peak, turning point, and end joints are each sustained for 32 msec. The combination of three peaks, four turning points, and six end points yielded 72 contours, each specified by a letter and two numbers (e.g., S24, L36) and each lasting 700 msec.

The 72 contours were recorded on magnetic tape from the output of the vocoder in three forms: (1) carried on a speech wave [no'vembs], (2) as a frequency-modulated sine wave, (3) as a frequency-modulated train of pulses. Each set of 72 was spliced into five different random orders with a five-second interval between stimuli and a ten-second pause after every tenth stimulus. They were presented to Swedish and U.S. subjects as described below.

---

1 One of the contentions of that study, based on a number of utterances in continuous speech by several Swedish subjects, was that every speaker has, in addition to a general speaking range, clusters of “favourite pitches” which he uses, for instance, on stressed segments of statements (represented by the H-peak in the present study), and a higher level which he uses for questions and various expressions of “interest” (here represented by level 4; cf. also Bolinger, 1964). Statements were found in that study to end on a low level, hesitant or exclamatory utterances, higher up. Questions tended to have a terminal rise, usually from level 2, or a fall ending comparatively high. Questions were also generally spoken with an overall high $f_0$ compared to statements, a phenomenon that, according to the literature, occurs in many languages (Hermann, 1942; Bolinger, 1964). The contour then often started high. Polite or friendly statements too might end with a final rise, but from a comparatively low level and with a moderate range (cf. Uldall, 1962).
Fig. 1. Schema of fundamental frequency contours imposed on the utterance "November" [no'vembə].

Swedish Subjects.

Twenty-two graduate and undergraduate volunteers were tested in three sessions, each lasting about 45 minutes. They listened to the tests over a loud speaker at a comfortable listening level in a quiet room. In a given session they heard the five test orders for one type of stimulus only. They were divided into two groups of 11. Both groups heard the sine-wave stimuli first; this was an important precaution intended to exclude any possible influence of speech mechanisms on judgments of the non-speech stimuli. In the second and third sessions both groups made psycho-physical or linguistic judgments on the speech stimuli, group 1 in the order psycho-physical-linguistic, group 2 in the reverse order. In the sine-wave session and in the psychophysical speech session, subjects were asked to listen to the final glide of each contour and judge whether it was rising or falling. In the linguistic speech session subjects were asked to judge each contour as more like a question or more like a statement. For each contour, the procedure yielded 5 judgments by each subject under each condition, a total of 110 judgments in all.

U.S. Subjects.

Sixteen female undergraduate paid volunteers were divided into two groups of eight. The procedure duplicated that followed with the Swedish subjects, except that the U.S. subjects listened to the tests over earphones in individual booths. The
output of the phones was adjusted by means of a calibration tone to be approximately 75 db. SPL. These subjects also made psychophysical judgments on the pulse-train stimuli; these were counterbalanced with the sine waves in the first two sessions before the speech stimuli had been heard. The procedure yielded a total of 80 judgments on each contour under each condition.

RESULTS

No systematic differences between groups due to the order in which they made their judgments were observed. Data are therefore presented for the combined groups throughout. Figs. 2 and 4 display the Swedish data, Figs. 3 and 5, the U.S. data. In each figure the left column gives the linguistic, the middle column the speech psychophysical, and the right column the sine-wave data. Percentages of question and statement judgments (linguistic) or of rise and fall judgments (speech psychophysical and sine-wave) are plotted against terminal glide, measured as rise (positive) or fall (negative) in c.p.s., from turning point to end point. In Figs. 2 and 3 parameters of the curves are $f_v$ values at peaks (S, H, L), displayed for the four turning-point $f_v$ values from 1 (top) to 4 (bottom). In Figs. 4 and 5 parameters of the curves are $f_v$ values at turning points (1, 2, 3, 4) displayed for the three peak $f_v$ values of S (top), H (middle), and L (bottom).

Linguistic Judgments

Cross-Language Comparisons

Before considering the acoustic variables controlling linguistic judgments, we will briefly compare Swedish and U.S. results. The main drift of the data is very similar for the two groups. A broad description of preferred statement and question contours for both groups can be given.

Statements. Fig. 6 schematizes the most frequently preferred contours, those obtaining 90% or better agreement. For all these contours, except two (L13; H13, Swedish only), the final $f_v$ of the terminal glide is the lowest $f_v$ of the utterance. In addition, the contours display at least one of the following: terminal fall, low or middle turning point (1, 2, 3), low or high peak (L, H). The range of preferred contours includes the 2 33 11 and 2 22 11 contours, suggested as typical by previous observations, but many others are equally acceptable. For example, the

Judgments of the modulated sine waves and pulse trains by U.S. subjects were essentially identical. Accordingly, only sine-wave data are presented here.

Fig. 6. Schemata of preferred statement and question contours. Included are all contours for which at least 90% of the judgments of a given language group were in a single category.
superhigh peak, even when followed by a high (S4, U.S. only) or moderately high (S3) turning point, is accepted as a statement provided the terminal fall is large enough; the lower the turning point (i.e., the larger the fall from the peak), the less the needed terminal fall (see S series, Figs. 4 and 5). On the other hand, some terminally level contours (H23, H12, L23, L12) and even terminally rising contours (H13, Swedish only; L13) are also accepted as statements. Evidently the terminal fall is not essential, if preceding sections of the contour are low enough (L) or are falling from a moderate level (H).

Broadly, then, peak, turning point, and terminal glide engage in trading relations such that the contour of an acceptable statement has a low to high (rarely, and for U.S. only, superhigh) peak and is, over some portion of its later course, low, falling, or both. (Two anomalous series, H4 and L4, are discussed below under Swedish-U.S. differences.)

Questions. Fig. 6 also schematizes contours obtaining 90% or better agreement on a question judgment. For all these contours, the terminal glide is rising and the final pitch of the glide is the highest of the utterance (cf. Uldall, 1962, p. 780; Majewski and Blasdell, 1969). The range of preferred contours includes the expected continuously rising 2, 22, 34* (L36, L46) and 2, 33, 37* (H46) of American English and the superhigh peak contour, 2, 44, 2* (S26) of Swedish, but other contours are also accepted. For example, initially low and falling contours (L1, L2) are heard as questions if the terminal rise is large enough. At the same time, even a terminally level contour (L45, Figs. 2-5) gathers more than 80% question judgments from both groups, when the preceding section of the contour has been steadily rising. In fact, this steady rise is a peculiarly powerful question cue that may quite override a large terminal fall that would otherwise cue a statement (cf. H4, L4, discussed below). Again there are trading relations among components of the contour, such that a generally accepted question displays either a rise from peak to turning point (H4, L3, L4) and a relatively small terminal rise, or a fall from peak to turning point and a relatively large terminal rise.

Swedish-U.S. differences. As we have seen, the similarities between Swedish and U.S. judgments are more striking than the differences. The stimulus series included a number of contours presumably unfamiliar to one or other or both groups from their linguistic experience. Yet both groups were able to generalize such contours with more familiar patterns, classifying contours with a relatively high overall pitch as questions, contours with a relatively low overall pitch as statements. Nonetheless, small systematic differences are present.

1) A comparison of Swedish and U.S. responses to the falling contours of the S2, S3, S4 series (Figs. 4 and 5, top left) shows that U.S. subjects tended to give more statement responses than Swedish subjects. The effect is particularly marked for the S4 series on which Swedish statement judgments never reach 90% agreement:
a high peak with a high turning point is difficult for Swedish subjects to hear as a statement. This may reflect the fact that Swedish statement intonation shows an earlier fall to a low level after stress than does English. At the same time, it may be taken as an indirect reflection of a Swedish preference for an overall high contour on questions, so that utterances displaying such a contour are difficult to hear as statements even when completed by a low terminal fall. It is true that the S4 series, which had been expected to collect a large number of question responses due to its overall high level, never obtained 90% agreement on a question judgment from either group. But a control of these items revealed that they gave an impression of protest or indignation rather than of questioning, probably because the low pre-contour was heard in opposition to the rest of the utterance. A pre-contour on level 3 might have eliminated this impression and would also have been more similar to what actually occurs in Swedish questions.

(2) As was remarked above, the continuously rising contours (L4 and, to some extent, L3 and H4; see Figs. 2 and 3, lower left) were readily accepted by both groups as questions, despite the fact that many of them are unlikely to occur in natural speech. L4, with its low peak rising 50 c.p.s. to the turning point, and H4, with its high peak rising 20 c.p.s., were preferred to L3 with its low peak rising only 15 c.p.s. Furthermore, H4 and, especially, L4 elicited relatively few statement responses, even when their terminal glides were falling sharply. U.S. subjects identified these contours as statements even less frequently than the Swedish group. This may reflect the fact that the steadily rising question contour is more widely used in American English than in Swedish and so might be peculiarly difficult for Americans to hear as a statement even when completed by a terminal fall.

In short, the differences between the two groups are small but in directions predictable from linguistic analysis.

Variables Controlling Linguistic Judgments

Terminal glide is the single most powerful determinant of linguistic judgments. None of the highly preferred question contours and few of the highly preferred statement contours (Fig. 6) lack the appropriate terminal rise or fall. Given a sufficiently extensive terminal glide, earlier sections of the contour have small importance. At the same time, Figs. 2-5 show that f values at peak and turning point may also play a role.

To provide a consistent criterion for the estimate of peak and turning-point effects, the median of the response distribution for each subject on each series was estimated. The median is the point of subjective equality, the value of the terminal glide at

We should probably have included a higher pre-contour, on level 3, to cover the question contours properly, since the large rise to the highest peak (from level 2 to level 4) gave some contours an unwanted and perhaps dominating effect of protest rather than question (cf. footnote 5.) However, this would have meant a substantial increase in an already lengthy test.
which subjects identify a given contour as a question or a statement 50% of the
time. In other words, it is the point of cross-over from largely statement to largely
question judgements. The means of these medians, or cross-over values, for the
judgments are plotted in Fig. 7 (row A) for Swedish subjects (left) and U.S. subjects
(right). In the first and third plots mean medians are graphed as functions of peak
f₀, with turning-point f₄ as parameter; in the second and fourth, they are graphed
as functions of turning-point f₄, with peak f₀ as parameter.

Two cautions should be observed in studying these plots. First it should be
remembered that a median is a single value drawn from the centre of its distribution.
The relation between the medians of two distributions does not always accurately
represent the relations between the upper and lower tails of those distributions. As
long as two curves on any plot of Figs. 2 to 5 are roughly parallel, the difference
between their medians will give a reasonable estimate of their separation along the
terminal glide axis. Where there are severe departures from the parallel, the
appropriate plots of Fig. 7 and of Figs. 2 to 5 should be carefully read in conjunction.
Second, it should be remembered that the mean of the medians of several distributions
is not necessarily equal to the median of the combined distribution. Since the values
of Fig. 7 are the means of subject medians, they do not always agree exactly with
the group median values read from Figs. 2 to 5.

With these precautions in mind we return to row A of Fig. 7. If the direction of
the terminal glide were the sole determinant of linguistic judgments, we would expect
all cross-over values to fall at zero, the level of the dashed horizontal lines across
Fig. 7. In fact, cross-over values deviate considerably from zero: both the direction
and the extent of their deviation vary with peak and turning point.

The peak effect (plots 1 and 3) is the smaller. For neither Swedish nor U.S.
subjects does a change of peak f₀ from 130 to 160 c.p.s. (from L to H) have any
consistent, significant effect. But a change from 160 to 200 c.p.s. (from H to S)
does reliably reduce the cross-over value for all contours, except that having a turning
point at 180 c.p.s. for the U.S. group. (This reversal is probably not reliable, as
study of the bottom left plot of Fig. 3 will suggest.) These effects are statistically
significant by matched pair t-tests between medians for turning points 1, 2, and 3
in both groups (p < 0.05). They may be clearly seen in the left columns of Figs. 2
and 3. Reading down the columns we note the leftward separation of the S curves.
The separation is reduced for turning point 3 and gives place to the L curve, with
its steadily rising contour, for turning point 4. We may also note that, as the terminal
rise increases, the peak effect in the upper three plots disappears. In short, if the
turning point is at a low to middle f₀ and the terminal rise is slight, a very high
(level 4) peak at the stress leads to a significant increase in the number of questions
heard and, by corollary, to a significant decrease in the number of statements.

The turning-point effect (plots 2 and 4 of Fig. 7) is both larger and more con-
sistent than the peak effect. For all values of peak f₀, an increase in turning-point f₄
is associated with a decrease in cross-over value. The decrease is significant by
matched pair t-tests between medians (p < 0.05) for all turning-point shifts, except
Fig. 7. Mean subject medians under the three experimental conditions for Swedish and American subjects. In the first and third columns, mean medians are plotted as functions of peak $f_p$, with turning-point $f_o$ as parameter; in the second and fourth columns, they are plotted as functions of turning-point $f_o$, with peak $f_p$ as parameter.
those from 100 to 120 c.p.s. for the Swedish S, H, and L curves and for the U.S. S and H curves. The effect is also considerably reduced, if the contour has a peak at 200 c.p.s. (S). (See top left plots of Figs. 4 and 5.) This again suggests that the high peak alone is a powerful question cue for both language groups.

Psychophysical Judgments

Speech Waves

Psychophysical judgments of the speech-wave terminal glides differ from and resemble linguistic judgments of the entire utterance in important ways. The main difference may be seen in the centre columns of Figs. 2 and 3: the effect of the high peak is absent from the Swedish data and much reduced in the U.S. data. The main similarity may be seen in the centre columns of Figs. 4 and 5: the turning-point effect is present and even more pronounced than in the linguistic judgments.

Fig. 7 (row B) summarizes the data. The peak effects (plots 1 and 3) are inconsistent. An increase in peak f, from 130 (L) to 160 c.p.s. (H) yields in every instance, except the high turning-point series for Swedish subjects, an increase rather than a decrease in the cross-over value of the terminal rise. Two of these increases (for turning points 1 and 2) are significant for both groups (p < 0.05 by a matched pair t-test between medians). On the other hand, an increase of peak f, from 160 to 200 c.p.s. yields, for the Swedish subjects, two increases and two decreases, none of them significant. The absence of a consistent peak effect for the Swedish subjects is evident in the middle column of Fig. 2. For the U.S. subjects, the picture is somewhat different: cross-over values decrease from H to S for turning points 1, 2, and 3 and increase for turning point 4, exactly as in the linguistic data. The effects are reduced and statistically significant only for turning point 2. But a trend is present and quite evident in the middle column of Fig. 3.

The turning-point effect, on the other hand (centre columns of Figs. 4 and 5; plots 2 and 4, row B of Fig. 1) is similar to and even more pronounced than the corresponding effect in the linguistic data. All shifts are significant by matched pair t-tests (p < 0.05), except that from turning point 1 to 2 in the Swedish L series. For both groups, the higher the turning point, the smaller the terminal rise needed for a rise to be consistently heard. The similarity to the linguistic results is most marked for the H and L series (second and third rows, Figs. 4 and 5): H4 and L4 are again anomalous series, readily heard as rising even when the terminal glide is falling. In the S series the turning-point effect is even more pronounced than for the linguistic judgments.

Sine Waves

From the steepled functions of Figs. 2 to 5 (right-hand columns) it is evident that subjects were in better agreement on their sine-wave than on their speech psycho-
physical or linguistic judgments. The two language groups are also in close agreement, which gives some confidence that the differences between their linguistic judgments are reliable.

Figs. 2 and 3 (right-hand columns) show that the effect of the high peak is absent. As in the speech psychophysical data, low peak contours tend to be the most accurately judged, particularly by the Swedish. But the effects are neither fully consistent nor statistically significant (see plots 1 and 3, row C, Fig. 7).

On the other hand, the turning-point effects (plots 2 and 4, row C, Fig. 7) are clear, similar to those observed in the linguistic and speech psychophysical data but considerably reduced. The effects are significant by matched pair t-tests \( p < 0.05 \) for all turning-point shifts, except those from 100 to 120 c.p.s. for the S and H curves in both groups, and may be seen in the right-hand columns of Figs. 4 and 5. Note that H4 and L4 are no longer anomalous series.

**Discussion**

*Cross-language comparisons.* There are striking similarities between Swedish and U.S. judgments of these intonation contours. Despite small, linguistically predictable differences, both groups tend to classify contours with a high peak or terminal rise as questions, contours with a low peak or terminal fall as statements. Hermann (1942) has pointed out the generality across languages, including Swedish, of a high pitch for questions (see also Hadding-Koch, 1961, especially pp. 119 ff.). Bolinger (1964), among others, has discussed the apparently "universal tendency" to use a raised tone to indicate points of "interest" within utterances and also to indicate that more is to follow, as in questions (cf. Hadding-Koch, 1965). The data of this experiment are consistent with these "universal tendencies."

*Perceptual relations within a contour.* We are now in a position to resolve some of the uncertainties left by our previous study. Consider, first, the turning-point effect. Since this is present and significant under all three experimental conditions, we must assign it auditory status and assume that it takes linguistic effect indirectly by altering subjects' perceptions of the terminal glide. Furthermore, since it is present, even though reduced, in the sine-wave data, our account of the process by which it affects perception of the terminal glide cannot invoke specialized mechanisms peculiar to speech.

We may gather some idea of the process from a study of plots 2 and 4 in row B, Fig. 7 or of the centre plots in Figs. 4 and 5. The terminal glide of a contour, such as H1, with a strong fall from peak to turning point (160 c.p.s. to 100 c.p.s.) requires a terminal rise of about 50 c.p.s. if it is to be judged 50% of the time as rising; while the terminal glide of a contour, such as H4, with a steady rise for more than 200 msec. before the terminal glide, is heard as rising 50% of the time, even when the glide is falling by about 50 c.p.s. Evidently listeners have difficulty in separating the terminal glide from earlier sections of the contour, if those earlier sections have
a marked movement. The terminal glides of contours with a turning point (145 c.p.s. in S3, H3, L3) close to the pre-contour level of 130 c.p.s. are more accurately perceived: the median values are close to zero in every plot of Fig. 7, columns 2 and 4. Listeners are perhaps able to average across earlier sections of such contours and establish an anchor against which terminal glide may be judged.

All this implies that later sections of the contours in this study (that is, roughly the last 400 msec., from peak to turning point to end point) were processed by listeners as a single unit, with attention focussed on the terminal glide. If a listener was able to separate the glide perceptually from the immediately preceding section (as in the S3, H3, L3 series), his linguistic judgments followed pretty well the traditional formulation of rise for questions, fall for statements. If he was not able to separate the glide, due to the difficulty—heightened perhaps for a complex speech signal—of tracking a rapidly modulated frequency, relatively gross movements of the terminal glide were necessary for him to be sure whether he had heard a rise or a fall, a question or a statement.

Interpretation of the peak effect is more difficult. In our earlier study, the effect was clear in both linguistic and psychophysical judgments of both groups, though the Swedish were less consistent in their psychophysical judgments than the Americans. In this study, a peak effect is significantly present in linguistic judgments, totally absent from sine-wave judgments, and for speech psychophysical judgments, marginally present only for the Americans.

We will consider the speech psychophysical data below. Here, the important point is that the peak effect is reliably present in the linguistic, but absent from the sine-wave, judgments. We may therefore, with reasonable certainty, reject an auditory (or psychophysical) account and assign a direct linguistic function to the peak. Unlike turning-point variations, peak variations do not take linguistic effect by altering listeners' perceptions of the terminal glide. Rather, the peak is a distinct element to be weighed with the perceived terminal glide in determining the linguistic outcome.

We should note, in caution, that peak and terminal glide are not always simply additive in their effects. For example, a contour with a steady rise from pre-contour to end point may require a relatively small terminal rise to be heard as a question, despite its low peak (e.g., L3 series). Here, it seems to be the overall sweep of the pattern that determines the judgment rather than the frequency levels of particular segments of the contour.

However, with few exceptions, two factors would seem to govern linguistic judgments of intonation contours, such as those of this study: fundamental frequency at the peak and perceived terminal glide. The entire contour is then interpreted as a unit with these factors in weighted combination, and with the heavier weight being assigned to the terminal glide. If a terminal fall is heard, the listener interprets the utterance as a statement, unless the fall was slight and he has also heard a very high peak; if a terminal rise is heard, the listener interprets the utterance as a question unless the rise was slight and he has also heard an unusually low peak (cf. Greenberg, 1969, Ch. 2; Ohala, 1970, pp. 101 ff.).
Auditory-linguistic interactions. We turn, finally, to the speech psychophysical data. Our problem is to understand the instances in which speech psychophysical judgments follow the linguistic more closely than the sine-wave judgments. Obviously these instances can only occur where linguistic judgments of the entire contour differ from auditory judgments of the terminal sine-wave glide, that is, where the contour carries some linguistically relevant cue other than terminal glide. For questions, such cues include a superhigh peak or a monotonic rise from pre-contour to turning point. Accordingly we find a tendency for speech psychophysical judgments to follow linguistic judgments in the superhigh (S) peak series (see Fig. 3) and in the high turning-point series (see Figs. 4 and 5). Consider, particularly, the results for speech contours of the H4 and L4 series. Listeners in both groups often judge these contours both as questions and as terminally rising, even though they are able to hear that the corresponding sine-wave contours have terminal falls. Since listeners cannot have judged the contours to be questions because they heard a terminal rise, we are tempted to conclude that they heard the terminal rise because they judged the contours to be questions: linguistic decision determined auditory shape.

Before elaborating on this, it is important to remark that such effects do not always occur where they might be expected. For example, the peak effect was clearly present in the speech psychophysical judgments of both groups in our earlier study but is reduced to a marginal effect in the American and has disappeared entirely from the Swedish speech psychophysical data of the present study. We can hardly therefore call on the effect to support a general account in terms of some specialized perceptual mechanism, such as that proposed by Lieberman (1967). At the same time, the results are evidently peculiar to speech and cannot be handled in purely auditory terms. What we need, therefore, is an account in terms of a process that may vary with experimental conditions and subjects.

An interesting hypothesis, suggested above, is that the results reflect the blend of serial and parallel processing that characterizes the perception of spoken language (and of other complex cognitive objects) (cf. Fry, 1956; Chistovich et al., 1968; Studdert-Kennedy, in press). We may conceive the perceptual process as divided into stages (auditory, phonetic, phonological, etc.), but we must also suppose there to be feedback from higher to lower levels which may serve to correct or verify earlier decisions. Perceptual “correction” of an auditory or phonetic decision, in light of a higher linguistic decision, will presumably not occur if the lower decision is firm. Otherwise, we would not be able to deem the intonation of an actor “wrong” or to understand a speaker, yet perceive his dialect to be unfamiliar. However, in difficult listening conditions and under certain, as yet undefined, acoustic conditions, perceptual “correction,” sufficient to produce a compelling phonetic illusion, may occur (Miller, 1956). Warren (1970; Warren and Obusek, 1971) has shown that listeners may clearly perceive a phonetic segment that has been excised from a recorded utterance and replaced by an extraneous sound ‘cough, buzz, tone’ of the same duration. The important point is that listeners perceive the correct segment: the precise form of the phonetic illusion is determined not by the acoustic conditions...
alone but also by higher-order linguistic constraints.

Here, the illusion is auditory rather than phonetic, but a similar mechanism may be at work. Asked to interrupt his normal perceptual process at a pre-phonetic auditory stage, the listener falls back on his knowledge of the language. As we have seen, the single most powerful cue for question/statement judgments in this experiment was the terminal glide. Listeners evidently prefer, and presumably expect, a question to end with a rise, a statement with a fall (see Fig. 6). However, earlier sections of the contour may also enter into the decision and, if sufficiently marked, override an incompatible, but relatively weak, terminal glide. Called upon to judge this glide, the listener then assigns it a value consonant with his linguistic decision. That is to say, if other factors dominate his linguistic decision, he may be led into non-verbatim perception of the terminal glide.

The degree to which this happens might be expected to vary with the relative strengths of the cues controlling linguistic decision. And in fact, just as the peak effect in the linguistic data was stronger for our first study than for our second, so too was the peak effect in the speech psychophysical data. Similarly, just as the question cue in the rising contours of the H4 and L4 series is stronger for the Americans than for the Swedish, so too is the tendency toward non-verbatim judgment of the terminal glide.

However, we should not expect to be able to develop a fully coherent account of our results in these terms, since we are ignorant of the limiting linguistic and acoustic conditions of the illusion. We are currently planning to broaden our understanding of the effect by taking advantage of what is known about the various acoustic cues to word stress (Fry, 1955, 1958). We might expect, for example, that, if linguistic decision can indeed determine auditory shape, syllables of equal duration, judged to be differently stressed on the basis of differences in either intensity or fundamental frequency, would also be judged of unequal length. The ultimate interest of the account is in its suggestion that the auditory level is not independent of higher levels but is an integral part of the process by which we construct our perceptions of spoken language.
